cacolico@my.cspc.edu.ph

Abstract

In this world we live in, Plants are one of the food security and agricultural productivity of humanity. With plant diseases that pose a significant threat to global food security, economic impact and agriculture movement. This proposed project focuses on a Digital Image Processing (DIP)-based approach for plant disease detection using image segmentation and feature extraction techniques. The methods crucially involve image processing, feature extraction to analyzed plant leaf images, and clustering methods. The images are processed to enhance the quality of the image and the disease regions part in the image will be more clearly seen and it is segmented based on color, its texture features. The results are yet to be identified but it is an approach of image processing by based analysis of patterns. It will determine to indicate whether the plant is healthy or is has disease this make a solution in agriculture, that offers reliable tools for farmers in automating diagnose plant diseases.

1 Introduction

In these times of years traditional disease detection inspection methods take a while, which adhere time consuming and error-prone results. This makes plant diseases pose danger to significant agriculture leading to economic loss and food loss, but with the advent of advancement many inventions and research are now relating this case study to advanced detection, especially with diseases. With Digital Image Processing systems provide an automated detection that is faster and is accurately alternative. This project focuses on images plant leaf as input this will use the image into segmentation and image processing techniques. The intake image of the plant is input processes through pre-processing where a noise reduction and contrast to image is applied, then segmentation technique model is used after that the input will make through feature extraction (color, texture, and shape analysis. Then by leveraging this step the output is predicted by category along with confidence score and accuracy score. By manipulating these steps with image processing, the system for identifying plant diagnosed is developed offering an efficient, cost-effective approach to plant disease diagnosis, aiding farmers in preventing and detecting such diseases.

2 Related work

The literature and studies that are relevant to this study are gathered in this section from a variety of sources, including Google Scholar, Academia, IEEE Xplore, ScienceDirect, and Research-Gate. These studies are important because they direct the researchers to develop the current study further. The studies that follow offer more details that aid the reader in comprehending this study.

In the current times the capabilities of image-based methods for plant disease identification and application to the real world is still wide. In the research study of Barbedo et al their studies focused on 82 different abiotic and biotic plants, it was revealed that advanced algorithm like image processing methods are still not robust enough to identify these based on histograms and transformations. In which methods proposed effort has been made by their team to achieve improve reliability and speed of the process like imaging techniques which they describe as multispectral and hyperspectral [2]. Analysis study of Dhingra et al. involves a like more disease diagnostics detection (phytopathology) where image processing has been applied to the image which they call a disproportionate process which is presented based on analysis findings [3]. This makes systems like this a need for quantifying severity to plants.

Similar study approach by Sinha and Shekhawat present a study approach of early detection in which feature images of all parts of plants is used, the images after applying segmentation techniques and other feature extraction was applied to be used with machine learning where a classification method was employed making it to detect early diseases for timely intervention [9]. Another study of Sena et.al suggests features like thresholding can detect pests in some plants. They presented that thresholder value offer to differentiate the difference between healthy and diseased plants [8]. Another study of Lloret et al suggest that by applying threshold on RGB and HSV color spaces it did find out the infected leaves and nutrient deficiency of vineyards plants [6]. This overview explains the characteristics of features used in image processing and how they are being used into methods.

According to Abdullah et.al. viable used of Machine learning without the used of segmentation is possible to detect typical plant disease. In their presented study, they augmented a based method of purely neural network that involves classifying techniques of statistical classifier and radial basis functions to backprogate in identifying diseases in some plants [1]. Vishnoi et. al conduct a study that suggest also that with Computer Vision and soft computing techniques were automated to detect plant diseases using leaf images [10]. This suggests that with the used of Machine learning systems contributed with the used of Image processing it is possible to process and detect plant diseases.

Further studies of Camperos et. al. focusing on crops disease, they did used various digital image processing such as pre-process, segmentation, features extraction and finally they used classification methods which is CNN (Convolutional Network) they find out increase in accuracy precision with the used of classification methods versus without classification [4]. Masahzar et.al proposed a classification technique using SVM multiclass classification that based through the leaf symptoms, they carried out SVM classifier in monitoring the palm oil at early stage making it to detect disease early [7]. Macedo-Cruz et al. suggest a developing method in oat crop prediction, in their study they worked on images relying on CIElab colour space, they combine three imaging techniques process the Otsu, isodata algorithms and fuzzy thresholding in predicting the damage extent of frost on oat crops [5].

Studies above clearly show a significant connection with the study. Digital Image are widely utilized in digitizing work, particularly those tasks that are performed manually and with the advent combination for future purposes of such Machine Learning theories and techniques. The use of Image processing in conjunction with plant images has been definitively proven to effectively identify and differentiate from their surroundings.

3 Methods

This section will outline the step-by-step approach using Digital Image Processing to identify plant diseases using image segmentation processing and other techniques. The model approach utilizes a image segmentation and feature extraction of key image inputs. The analysis of input images involves processing techniques such as color space conversion, edge detection, and texture analysis to extract crucial characteristics like leaf texture, color variations, and lesion patterns. With the use of image segmentation, feature extraction, and rule-based analysis to determine patterns that indicate disease.

Preprocessing techniques such as noise removal, contrast enhancement, and normalization of the image input enhancing model generalization will be applied to improve quality. Loss function that is yet to be finalized which is likely to be used is the method cross -entropy loss function that will be measuring the difference between the predicted and actual class labels and is trained using Gradient Descent. Segmentation methods, including thresholding and edge detection will be used to isolate diseased regions.

The model effectiveness is measured through accuracy, precision, metrics and ROC curves. After assessing the trained system, it will be deployed to implement in identifying plant diseases and early disease prevention. Feature extraction techniques will analyze color, texture, and shape attributes to classify the plant leaves. Instead of a machine learning classifier, a rule-based decision system will determine the disease type based on extracted features and predefined thresholds.

3.1 Data Preprocessing and Augmentation

The images categorized into different plants, approximately 87000 RGB images that is both healthy and diseased plant leaves, categorized into 38 different classes. While these are the information of the images it is not sure if all of them will be read by the time the image will be extracted. wherein approximately 33 images will be used for validation and testing.

CLASSIFICATION	No. of IMAGES	Structure Identity
Plant Images	- 87,000 imges	/Plant/{Class_Name}/image.jpg
Test Set	- 33 images	/test/image.jpg

The 33 images on test set is not included in the 87,000 images instead the 33 images will be the test set that is for evaluating the accuracy or performance test in processing the Digital image whether it is healthy or disease plant. Images are imported utilizing OpenCV or scikit-image, each image is resize and applies normalization to enhance generalization.

3.2 Proposed Model

The proposed model utilizes Digital Image Processing (DIP) techniques for plant disease detection. Instead of deep learning, this approach relies on image segmentation, color analysis, edge detection, and thresholding operations to identify diseased regions in plant leaves.

MODEL ARCHITECTURE

Fig. 3.2 Image processing model in Plant disease

3.4 Digital Imaging Process

The proposed model utilizes Digital Image Processing (DIP) techniques for plant disease detection. Instead of deep learning, this approach relies on image segmentation, color analysis, edge detection, and thresholding operations to identify diseased regions in plant leaves.

3.4.1. Image Acquisition and Pre-processing

The process began with the acquisition of the image. Then. operation of pre-process began to perform, the image acquired use a enhancing techniques to remove unwanted distortions enhancing its characteristics for processing. In image pre-processing image quality enhancement techniques are applied to reduce any noise and make the image sharpen and improve its quality for greater quality. Improving the image quality for better obtainable detection and classification of disease for any sort part of plants.

3.4.2. Segmentation

Next process is segmentation, which is applied to the color-converted image to separate the object of interest from the background. These steps involves extensive operations including division, multiplication and averaging resulting in significant increase in execution due to its computational complexity.

3.4.3 Feature Extraction

This process plays an important role in image processing. Feature extraction processes are employed to obtain attributes for image processing recognition and classification. A feature set contains information that helps differentiate of what through the image was. This generally uses two categories which is the shape feature and texture feature extraction.

Shape Feature Extraction:

Image processing techniques including Sobel-edge detection algorithms, morphological operations are applied to this feature to extract shape related features. Extracted shape features that is possibly stored in feature extraction is its perimeter, major and minor axis length, eccentricity, solidity, shape factor, compactness.

Texture Feature Extraction:

This feature represents the properties featured based on its target pixels, texture, group pixel, characteristics like its contrast and entropy form. With this it can be categorized for its spatial texture and texture features extraction.

3.4.4 Post Classification

Apply threshold classification will rules based on the observed characteristics of spots of the diseased plants. This work is believed to worked on the future works for this research by setting numerical thresholds for different features like its color, texture, or shape to distinguish disease and healthy region parts of the plants.

3.5 Disease classification

The classification based decision is by defining on predefined IF-ELSE, where texture and pattern has certain threshold that indicate fungal infection of the plant (eg. yellowing patterns suggesting that it has nutrient deficiencies).

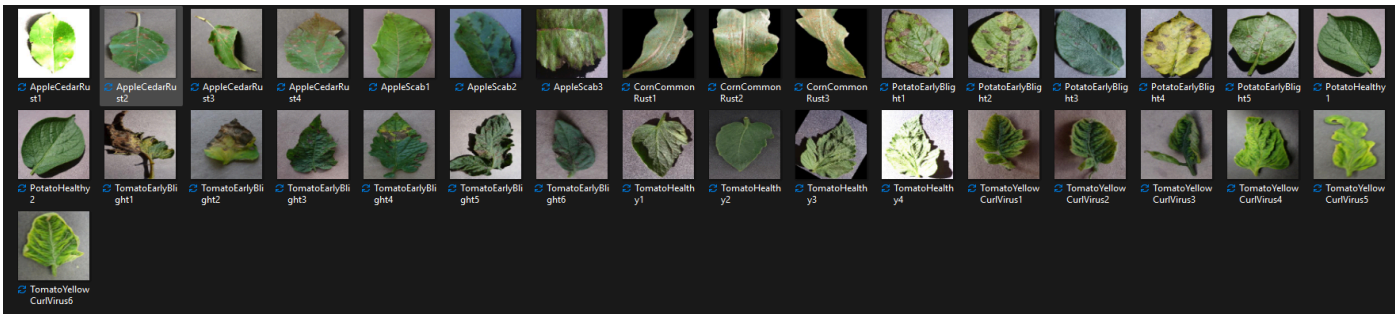

The process begins with feature extraction, where characteristics such as color variations, texture irregularities, and shape distortions in the leaf are analyzed using techniques like histogram analysis, edge detection, and morphological operations. Threshold-based decision-making is then applied by defining specific limits to differentiate healthy leaves from diseased ones.

4 Results and Discussion

This section presents the outcomes of the implemented plant disease detection system using image segmentation and rule-based analysis. The primary objective was to classify plants images as either “Healthy”or “Diseased" without the use of machine learning models. The image used here has already been tested by experts, so the image was already classified as healthy or has a disease instead the implementation will classify based on key features values derived from visual features.

The dataset contains features extracted from images of test_image categorized as blight, rust, scrabble,early, virus, and healthy. Key features analyzed include area, perimeter, entropy, and mean RGB color intensities.

Feature Discussion:

Area and Perimeter: Disease leaves generally exhibit larger areas compared to healthy ones. This reflects the clustering of disease spots, which increase the overall affected leaf surface and edge complexity of the image.

Entropy: This feature measures the randomness or texture complexity of the image; higher values may suggest more irregular patterns consistent with disease symptoms such as spots, rusts or scabs disrupting the uniform texture of the leaf surface.

Color Intensities: The color features also differentiated the two groups. Diseased leaves tended to have higher mean red and green channel intensities, reflecting discoloration patterns typical of lead diseases.

The image processing techniques used in this project followed a classical Digital Image Processing. The methods applied using Python (OpenCv, Numpy, OS, Seasborn etc.) in Jupyter Notebook in VSCODE.

COLLEGE of COMPUTER STUDIES

CSAC 224 - Machine Learning

Feature Extraction - from the segmented region, many main features were extracted these key feature helps in determining the classification of the plant:

Area - Total pixel count of the infected region
Perimeter - Total length boundary if a segmented object
Entropy - Texture descriptor indicating the randomness or complexity in pixel values
Color Intensities - Average intensity of color in the segmented region

Classification Rule

```python
# Step 3: Define the rule-based classifier
def classify_disease(features):
    if (3.6 <= features['entropy'] <= 4.75 and
        65 <= features['mean_red'] <= 195 and
        38000 <= features['area'] <= 51000):
        return "Healthy"
    else:
        return "Diseased"
```

This image above shows the rule-based classifier on statistical thresholds derived from visual and numerical analysis of healthy vs.diseased samples.

Output

The system was tested on multiple plant images with "Known" ground truth-labels (disease_status) for evaluation. The (predicted_status) from the rule based classification were compared to the actual labels.

	filename	disease_status	predicted_status
0	AppleCedarRust1.JPG	Diseased	Diseased
1	AppleCedarRust2.JPG	Diseased	Diseased
2	AppleCedarRust3.JPG	Diseased	Diseased
3	AppleCedarRust4.JPG	Diseased	Diseased
4	AppleScab1.JPG	Diseased	Diseased
5	AppleScab2.JPG	Diseased	Diseased
6	AppleScab3.JPG	Diseased	Diseased
7	CornCommonRust1.JPG	Diseased	Diseased
8	CornCommonRust2.JPG	Diseased	Diseased
9	CornCommonRust3.JPG	Diseased	Diseased

classification accuracy was calculated using:

```
accuracy = (df['disease_status'] == df['predicted_status']).mean()
```

From the usage of the known 33 images sample, here is the output result:

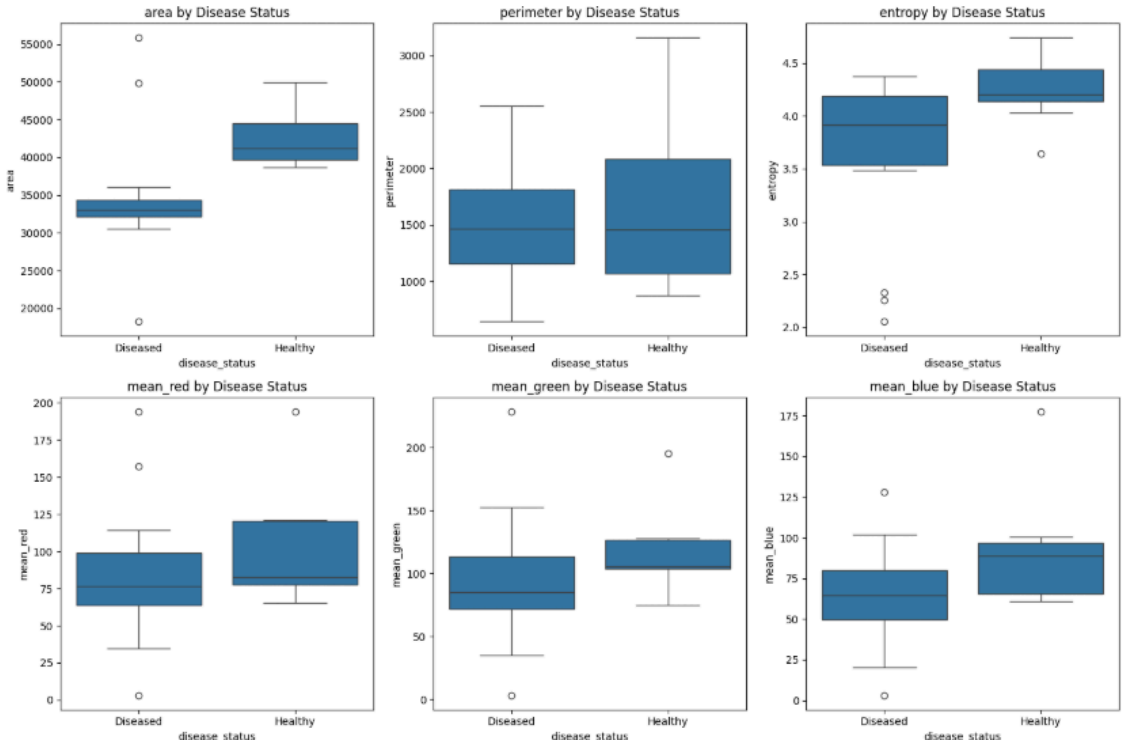

```
✅ Classification Accuracy: 90.91%

Confusion Matrix:
Predicted  Diseased  Healthy
Actual
Diseased         24        3
Healthy           0        6
```

The results indicate that the rule-based system performs well under the selected thresholds, **achieving high overall accuracy (90.91%).** Specifically:

- All **healthy** samples were correctly classified.
- Most **diseased** samples were correctly identified, with only a small number misclassified as healthy.

This is because the classification rule, ruled out that the Early blight has its range as a healthy plant, which is somehow still healthy. Where in by label it is labeled as Diseased.

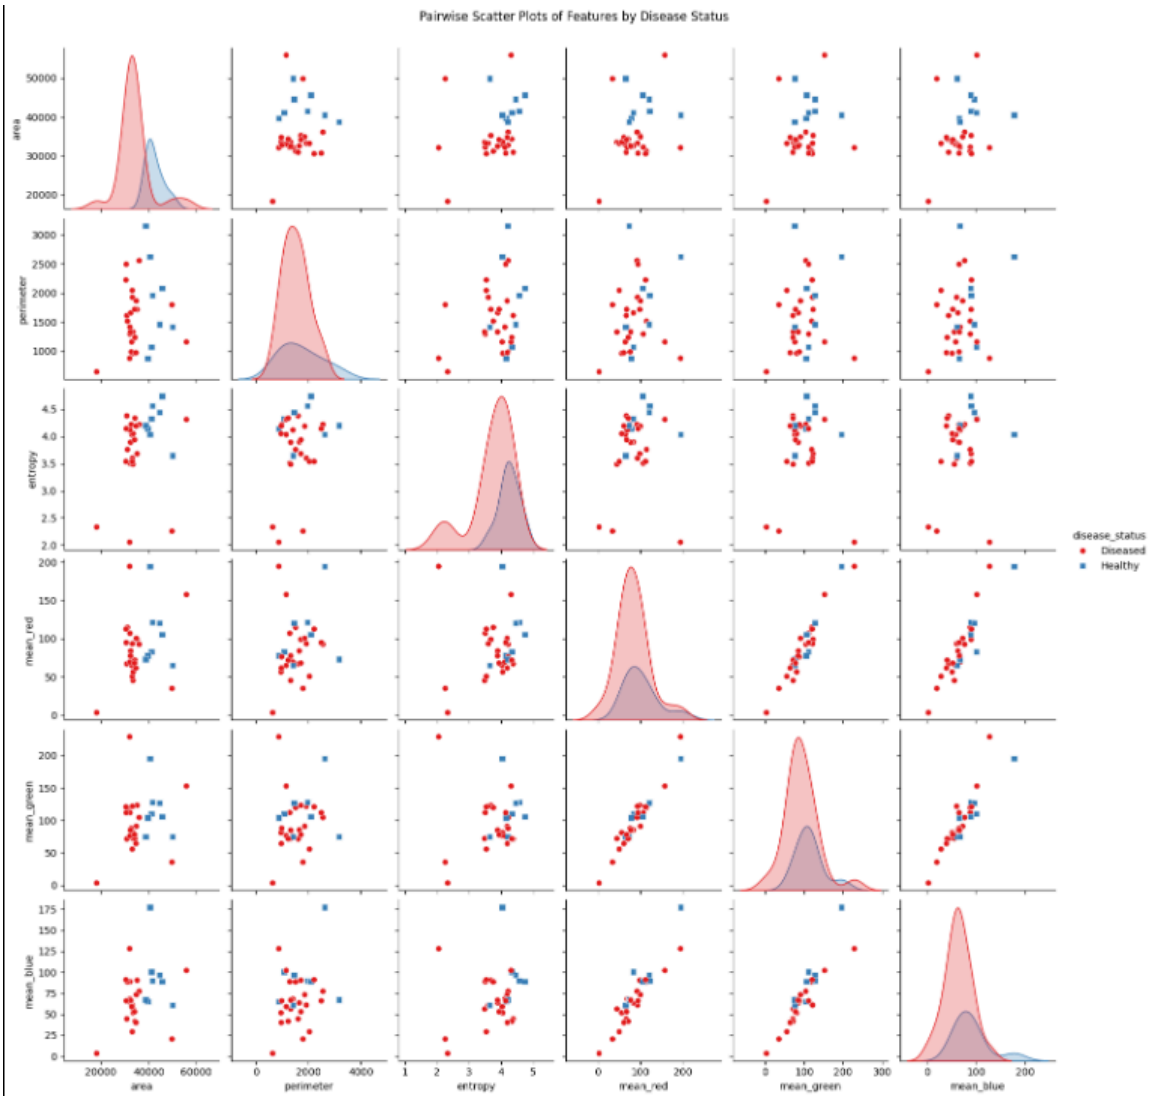

This performance suggests that the selected entropy, area, and red-value thresholds are well-suited for the current dataset. The **zero false positives** (no healthy sample misclassified as diseased) highlight the system's reliability in confirming healthy plants, which is valuable in real-world agricultural screening.

A total of 33 leaf images were processed. The classifier categorized 9 samples (27.27%) as Healthy and 24 samples (72.73%) as Diseased.

Analysis showed diseased leaves have a higher mean entropy (3.73) compared to healthy leaves (4.25). Mean leaf area was 34034.71 pixels for diseased and 42362.28 pixels for healthy samples.

CSAC 224 - Machine Learning

Diseased leaves generally exhibit higher entropy and wider variation in color intensities, particularly in the green and blue channels. A positive correlation is evident between area and perimeter, as well as among the RGB values. While some feature overlap exists between healthy and diseased samples, the visual separation, especially in entropy and color metrics, supports their effectiveness in distinguishing leaf health status.

5 Summary/Conclusion

This project focused on plant disease detection using image segmentation and a rule-based analysis approach. By extracting key image features such as **area**, **perimeter**, **entropy**, and **mean color values (RGB)**, the system was able to classify plant leaves as *Diseased* or *Healthy* without relying on machine learning or deep learning models. The achieved classification accuracy of **90.91%** reflects the effectiveness of rule-based techniques when combined with proper image preprocessing and feature extraction. The confusion matrix also indicated a strong performance in detecting diseased leaves. Feature scatter plots revealed distinguishable patterns between healthy and diseased leaves, particularly in **color intensity**, **area**, and **perimeter**, validating the importance of these features. Although limited by hardware constraints, the current results demonstrate that a well-designed, traditional image processing pipeline can still yield high accuracy in real-world agricultural applications. Future work may involve extending the rule set or integrating lightweight machine learning to enhance adaptability and scalability.
